(54) **Semiconductor device for use in a light valve device, and process for manufacturing the same.**

(57) The present invention provides a semiconductor device for use in a light valve (e.g. in an LCD display) and a process for producing the same. The semiconductor device has a support layer (14,15) with transistor elements (5-7) provided thereon. The semiconductor device is characterised by a thin film layer (1) including a surface insulating film (3), a single crystal semiconductor thin film (4) disposed below said surface insulating film and having a source region (6), a drain region (7) and a channel forming region (5) for constituting each said transistor element, an insulating film (8) disposed on the side of the single crystal semiconductor thin film opposed to said surface insulating film for providing a gate insulator, an electrode film (9) disposed on the side of the insulating film opposed to said single crystal semiconductor thin film for providing a gate electrode of each said transistor element, and a back insulating film (10) disposed at least over the electrode film on the side thereof opposed to said insulating film, said support layer being fixedly adhered in face to face relation with said

back insulating film. The process for manufacturing the device comprises a first step of forming an SOI substrate having a single crystal semiconductor thin film (22; Fig. 15) laminated on a tentative substrate (20) through an insulating film (21); a second step of forming a semiconductor integrated circuit for said single crystal semiconductor thin film; a third step of adhering a support substrate (24,25) fixedly in face to face relation with the surface of the semiconductor integrated circuit opposite the side of the tentative substrate; a fourth step of removing the tentative substrate to expose the insulating film (21) to the outside; and a fifth step of subjecting exposed surface of the insulating film to a treatment including at least the forming of an electrode.

EP 0 486 318 A1

FIG. 10

The present invention relates to a semiconductor device for use in a light valve device, and to a process for manufacturing the same.

In a prior art active matrix device, thin film transistors are formed on the surface of an amorphous silicon thin film or a polycrystalline silicon thin film deposited over a glass substrate. The transistor elements formed on the amorphous or polycrystalline silicon thin film are generally of a field effect insulated gate type. The amorphous silicon thin film or the polycrystalline silicon thin film can easily be deposited over the glass substrate by chemical vapour deposition so that the structure is suited for manufacturing an active matrix liquid crystal display device having a relatively large frame. At present, a commercially produced active matrix liquid crystal display device using the amorphous silicon has an area of about 3" (7.62 cm) to 10" (25.4 cm). The amorphous silicon thin film is suitable for a liquid crystal panel having a large area because it can be formed at a low temperature equal to or less than 350°. On the other hand, an active matrix liquid crystal display device using the polycrystalline silicon thin film is commercially produced at present with a small size liquid crystal display panel as wide as about 2" (5.08 cm).

However, while the prior art active matrix liquid crystal display device using the amorphous silicon thin film or the polycrystalline silicon thin film is suitable for a direct viewing type of display device requiring a relatively large frame and image plane, it is not always suitable for a miniaturized device in which the density of the pixels is increased. The demand for a microminiature display device or a light valve device having a fine and highly dense arrangement of pixels has increased in recent years. Such a microminiaturized light valve device is utilized in the primary image forming plane of a projection type of imaging device, for example, and may be applied to a projection type of high definition TV system. The fine semiconductor manufacturing technology can be used to manufacture a microminiature light valve device which has a pixel size in the order of 10 μm and a total size of about several cm.

In cases, however, where the amorphous or polycrystalline silicon thin film according to the prior art are used, transistor elements of the order of sub-microns cannot be formed by fine semiconductor processing technology. Since the amorphous silicon thin film, for example, has a mobility of about 1 $\text{cm}^2/\text{Vsec.}$, a driver circuit required to have a high speed operation cannot be formed over a common substrate. In the case of the polycrystalline silicon thin film, on the other hand, the crystal particle has a size of about several μm , thus necessarily raising a problem that the miniaturization of active elements is restricted.

An alternative semiconductor device, which is widely available, has its transistor elements formed on the surface of a single crystal substrate. Figure 2

is a section showing such a semiconductor device. Generally speaking, the semiconductor device comprises a single crystal semiconductor substrate 101 made of silicon.

Specifically, the single crystal semiconductor substrate 101 has its surface formed integrally and highly densely with transistor elements or the like by impurity diffusion and a film forming process. In the example shown in Figure 2, the single crystal semiconductor substrate 101 has insulated gate field effect transistors formed thereover. Each element region to be formed with a transistor is enclosed by a field insulated film 102. The element region is formed with a source region 103 and a drain region 104 by the impurity doping process. Between the source region 103 and drain region 104 there is formed a region 105 for forming the channel of the transistor. This channel forming region 105 has a gate electrode 107 formed thereabove over a gate oxide film 106. The transistor element composed of the gate electrode 107, the source region 103, the drain region 104 and so on is covered with an interlayer insulating film 108. A source electrode 109 and a drain electrode 110 for wiring the individual transistors extend through contact holes formed in the interlayer insulating film 108.

The prior art semiconductor device including a substrate made of the silicon single crystal, as described above, is superior, in the high speed of its operation and the high density of the transistor elements and so on, to the aforementioned amorphous silicon thin film and polycrystalline silicon thin film semiconductor devices.

Since, however, the silicon single crystal substrate is opaque, it cannot be employed as it is in a device, such as a light valve device, requiring a transparent substrate.

In recent years, on the other hand, an image projection system using a light valve device has begun to be employed. This image projection system is desired to have a smaller size, less weight and a finer projection image. Accordingly, an integrated circuit of the semiconductor device for use in the light valve device is required to have a far higher density.

Incidentally, the prior art semiconductor device is formed with the transistor elements by subjecting one face of the single crystal semiconductor substrate 101 sequentially to the impurity doping process and the film forming process. These processes are always carried out from one face only so that the films are sequentially laminated. As a result, once the lower layer is processed and laminated with an upper layer, it cannot be subjected to an additional treatment anymore, thus raising a problem that the step design is restricted in various points.

Although the semiconductor substrate 101 has a front surface and a back surface opposed to each other, the semiconductor device is formed by making use of the front surface of the semiconductor sub-

strate 101 only. Thus, the wiring of an integrated circuit is concentrated only at the front surface while leaving the back surface unused. As a result, an area restriction is imposed on the wiring density, which raises a problem that a far higher density of the integrated circuit cannot be expected. If the back surface of the semiconductor substrate could be utilized as the wiring face, the integration density could be effectively doubled. Nevertheless, this two-face wiring has been impossible with the prior art structure.

In order to raise the integration density, it has also been proposed to wire multiple layers on one face of the semiconductor substrate. With these multi-wiring operations, however, the flatness of the semiconductor substrate surface is degraded, which raises a problem that an open defect arises in step portions or another short-circuit defect occurs.

In the structure of the prior art, the transistor elements are directly integrated on the front surface of the single crystal semiconductor substrate. As a result, this single crystal semiconductor substrate is in an integral relation with the transistor elements formed thereover. In other words, the integrated circuit is always supported by the single crystal semiconductor substrate. Depending upon the intended application of the semiconductor device, however, the use of the single crystal semiconductor substrate as the support substrate is frequently improper. Since this support substrate cannot be freely set, the existing structure has a problem in that there is no flexibility in the application range of the semiconductor device.

In view of the problems of the aforementioned various prior art arrangements, it is an object of the present invention to provide a semiconductor device in which a single crystal semiconductor thin film can have both of its faces processed to make double sided wiring possible.

The invention achieves this by adhering the single crystal semiconductor thin film through an insulating film to a support substrate, preferably made of the same material as the semiconductor single crystal thin film, to form electrodes and various elements over the single crystal semiconductor thin film, and by subsequently removing the support substrate to form further electrodes and so on over the insulating film too.

According to the present invention, there is provided a semiconductor device having a support layer with transistor elements provided thereon, characterised by a thin film layer including a surface insulating film, a single crystal semiconductor thin film disposed below said surface insulating film and having a source region, a drain region and a channel forming region for constituting each said transistor element, an insulating film disposed on the side of the single crystal semiconductor thin film opposed to said surface insulating film for providing a gate insulator, an electrode film disposed on the side of the insulating film opposed to

said single crystal semiconductor thin film for providing a gate electrode of each said transistor element, and a back insulating film disposed at least over the electrode film on the side thereof opposed to said insulating film, said support layer being fixedly adhered in face to face relation with said back insulating film.

By means of the invention, it is possible to provide a highly dense semiconductor device having a stable operation.

The support layer may be a two layer structure including a support substrate fixedly adhered in face to face relation to the back insulating film by way of an adhesive film. Alternatively, the support layer may be a single layer structure moulded from an adhesive material.

Advantageously, the support layer is made of an optically transparent material.

Each transistor element preferably comprises a source region and a drain region formed in the single crystal semiconductor thin film in self-alignment with the gate electrode.

The channel forming region of each transistor element may conveniently have its conductivity set selectively by the selective introduction of an impurity through the surface insulating film during production.

According to another aspect of the present invention, there is provided a process for manufacturing a semiconductor device characterised by a first step of forming an SOI substrate having a single crystal semiconductor thin film laminated on a tentative substrate through an insulating film; a second step of forming a semiconductor integrated circuit for said single crystal semiconductor thin film; a third step of adhering a support substrate fixedly in face to face relation with the surface of the semiconductor integrated circuit opposite the side of the tentative substrate; a fourth step of removing the tentative substrate to expose the insulating film to the outside; and a fifth step of subjecting the exposed surface of the insulating film to a treatment including at least the forming of an electrode.

Another object of the present invention is to provide a light valve device having a large capacity and capable of displaying a fine image.

According to this aspect of the present invention, there is provided a light valve device comprising a drive substrate having drive electrodes and drive circuits for exciting said drive electrodes in response to predetermined signals; an opposed substrate arranged opposite to said drive substrate; and an electro-optical material layer arranged between said drive substrate and said opposed substrate, characterised in that said drive substrate includes a transparent insulating film layer and a single crystal semiconductor thin film formed over said transparent insulating thin film layer, said drive circuits include transistor elements formed in said transparent

insulating thin film layer, and said drive electrodes are integrally arranged on said single crystal thin film layer and electrically connected with said drive circuits whereby they are excitable by said drive circuits to act upon said electro-optical material layer for controlling the optical transparency of the same.

Advantageously, optical leakage of the transistor element is prevented by forming a light shielding film on that surface of the transparent insulating thin film layer which is opposed to the surface formed with the single crystal semiconductor thin film layer so as to cover at least the active regions of the transistor elements.

The light shielding layer may be formed from an opaque conductive material and may have a portion overlapping the drive electrodes through the transparent insulating thin film layer so as to form capacitor elements between the light shielding layer and the drive electrodes.

Preferably, the drive electrodes are formed over the transparent insulating thin film layer in portions from which the single crystal semiconductor thin film layer has been removed.

In one embodiment, the drive substrate has a laminated structure including the transparent insulating thin film layer, the single crystal semiconductor thin film layer formed over the transparent insulating thin film layer, and a support substrate fixed in face to face relation to the single crystal semiconductor thin film layer through an adhesive layer, with the opposed substrate and the electro-optical material layer being arranged at the side of the transparent insulating thin film layer.

In another embodiment, the drive substrate has a laminated structure including the transparent insulating thin film layer, and a support substrate fixed through an adhesive layer to that side of the transparent insulating thin film layer which is opposed to the side formed with the single crystal semiconductor thin film layer, the opposed substrate and the electro-optical substance layer being arranged at the side of the single crystal semiconductor thin film layer.

In the embodiments described below, the electro-optical material layer is a liquid crystal layer. For example, the electro-optical material layer may be a polymer dispersion liquid crystal layer in which a liquid crystal is dispersed in a polymer material.

The drive electrodes of the light valve device may be pixel electrodes arranged in matrix formation, and the drive circuits may then include switching elements also arranged in matrix formation, with the pixel electrodes being electrically connected with the switching elements so as to be selectively excitable by the switching elements.

In this instance, the drive circuits may further include scanning circuits for scanning the switching elements. The drive circuits may also include image signal processor circuits for processing image signals

input from the exterior for supply to the scanning circuits.

As described, an electrode pad may be formed at that surface of the transparent insulating thin film layer which is opposed to the surface arranged with the single crystal semi-conductor thin film, and the transparent insulating thin film layer may be formed with contact holes through which the drive circuits formed in the single crystal semiconductor thin film and the electrode pad are electrically connected.

Preferably, the transistor elements are insulated gate transistor elements, and portions of the single crystal semiconductor thin film between the channel regions of the insulated gate transistor elements and the transparent insulating thin film layer are electrically grounded to earth.

One of the drive substrate and the opposed substrate may be formed thereover with a colour filter for a colour display.

According to a further aspect of the present invention, there is provided a process for manufacturing a light valve device having a semiconductor substrate, characterised by a first step of preparing a three layer substrate, in which a temporary substrate and a single crystal semiconductor thin film layer are laminated through a transparent insulating thin film layer; a second step of forming pixel electrodes in portions of said three layer substrate from which the single crystal semiconductor thin film layer is selectively removed, and forming said single crystal semiconductor thin film layer with drive circuits composed of switch elements and driver circuits for supplying signals selectively to said switch elements; a third step of adhering a carrier substrate on the surface of said three layer substrate which is formed with said pixel electrodes and said drive circuits; a fourth step of removing said temporary substrate to expose said transparent insulating thin film layer; a fifth step of forming through holes in predetermined locations in said exposed transparent insulating thin film layer and forming a metal film on the exposed surface of said transparent insulating thin film layer; a sixth step of removing said metal film to form a light shielding layer for covering at least a portion of said drive circuits and forming an electrode pad connected with said drive circuits by way of said through holes to form said semiconductor substrate; and a seventh step of laminating and adhering the surface of said semiconductor substrate formed with said light shielding layer and an opposed substrate formed with a transparent electrode so as to leave a gap between said substances and filling up said gap with an electro-optical material.

According to a still further aspect of the present invention, there is provided an image projection system comprising a light source; a light valve device for guiding light coming from said light source, said light valve device comprising a drive substrate having drive electrodes and drive circuits for exciting said

drive electrodes in response to predetermined signals, an opposed substrate arranged opposite to said drive substrate, and an electro-optical substance layer arranged between said drive substrate and said opposed substrate; and an optical lens for magnifying and projecting an image on said light valve device; characterised in that said drive substrate of said light valve device includes a transparent insulating thin film layer, a single crystal semiconductor thin film layer formed over said transparent insulating thin film layer, and a light shielding layer formed at the surface of said transparent insulating thin film layer which is opposed to the side of said single crystal semiconductor thin film layer, said drive circuit includes transistor elements formed in said transparent insulating thin film layer, said light shielding layer is formed to cover the active portions of said transistor elements, and said drive electrodes are integrally arranged on said single crystal thin film layer and electrically connected with said drive circuits so that they are excited by said drive circuits to act upon said electro-optical substance layer whereby to control the optical transparency of the same.

The present invention will be described further, by way of example, with reference to the accompanying drawings, in which:-

Figure 28 shows a nineteenth embodiment according to the present invention and is a section for explaining an image projection system using a light valve device.

Figure 1 is a section showing a portion of a basic structure of a semiconductor device according to the present invention. As shown, a semiconductor device according to the present invention is composed of a thin film laminated layer 1 formed integrally with transistor elements and a support layer 2 for supporting the thin film laminated layer 1. This thin film laminated layer 1 has a surface insulating film 3 having a flat face to be formed with electrodes. Below this surface insulating film 3, there is arranged a single crystal semiconductor thin film 4. This single crystal semiconductor thin film 4 is formed not only with a channel forming region 5 for each transistor element but also with a source region 6 and a drain region 7 which merge into the channel forming region 5. Below the single crystal semiconductor thin film 4, there is arranged through a gate oxide layer 8 an intermediate electrode film which forms a gate electrode 9 of the transistor element. Below said intermediate electrode film, moreover, there is arranged a back layer film 10. This back layer film 10 is formed with contact holes which extend to the source region 6 and the drain region 7 so that a source electrode 11 and a drain electrode 12 are arranged therethrough. The source

electrode 11 and drain electrode 12 are wired all over one face of the back layer film 10. Incidentally, this back layer film 10 is composed of a field insulating layer 13 surrounding an element region to be formed with the transistor element and an insulating layer covering the gate electrode 9. The thin film laminated layer 1 thus far described is supported by the support layer 2. In other words, this support layer 2 is fixedly adhered in face-to-face relation to the back layer film 10.

Preferably, said support layer 2 has a two-layer structure composed of an adhesive film 14 applied to the back layer film 10 and a support substrate 15 fixedly adhered in face-to-face relation by the adhesive film 14. Alternatively, the support layer 2 may have a single-layer structure moulded of an adhesive. The adhesive to be used for this fixed face adhesion can be a fluid material composed mainly of silicon dioxide, for example. The support substrate 15 may be formed in advance with through holes for releasing the gas which is generated during a heat treatment of the adhesive. Moreover, the material for the support substrate 15 may be freely selected from an optically transparent material such as quartz in addition to the semiconductor such as silicon.

Each of the transistor elements formed integrally in the thin film laminated layer 1 has the source region 6 and the drain region 7, which are formed in the single crystal semiconductor thin film in self-alignment with the gate electrode 9. The surface insulating film 3 positioned over the single crystal semiconductor thin film 4 and formed with the channel forming region 5, the source region 6 and the drain region 7 has a flat face so that it can be freely formed, if necessary, with a variety of electrodes. For example, a capacity element can be formed in the surface insulating film 3, by forming an opposed electrode over the surface insulating film 3 such that it is opposed to the drain region 7. Then, it is possible to manufacture a semiconductor device having a DRAM structure. Alternatively, a transparent electrode can be so formed over said surface insulating film 3 that it is electrically connected with the drain region 7 to form a pixel. The semiconductor device having such structure can be applied as a drive substrate for a light valve. Through the contact holes formed to extend through the surface insulating film 3, furthermore, there may be formed over the surface insulating film 3 a wiring electrode which is connected with the terminal portion of each transistor element. Then, the wiring of the integrated circuit can be accomplished on the two faces of the thin film laminated layer 1 to improve the effective wiring density. Alternatively, an optical leakage preventing shielding film can be formed over said surface insulating film 3 so as to cover at least the channel forming region 5 of each transistor element formed in the single crystal semiconductor thin film 4. Moreover, an additional gate electrode can be formed

over said surface insulating film 3 such that it is aligned with the channel forming region 5 of each transistor element formed in the single crystal semiconductor thin film 4. The performance of the transistor can be improved by controlling the channel forming region 5 by a pair of opposed gate electrodes. Furthermore, a pad electrode for external connection can be formed over the surface insulating film 3. Since this pad electrode has a relatively large area, the packaging density of the integrated circuit can be substantially improved by separating it from the wiring line of the integrated circuit at the back and arranging it on the surface.

The channel forming region 5 formed in the single crystal semiconductor thin film 4 can be processed from the side of the surface insulating film 3. By doping the channel forming region 5 selectively with an impurity through the surface insulating film 3, for example, the conductivity of the channel forming region 5 can be set individually and selectively. Thus, it is possible to provide a semiconductor device having an MROM structure.

Next, a process for manufacturing the semiconductor device having the basic structure shown in Figure 1 will be described with reference to Figures 15(a) to 15(c). First of all, a first step is performed (as shown in Figure 15(a)) for forming an SOI substrate 23 which has a single crystal semiconductor thin film 22 laminated over a tentative substrate 20 through an insulating film 21. Next, a second step is performed for forming a semiconductor integrated circuit with respect to said single crystal semiconductor thin film 22. Subsequently, a third step is performed (as shown in Figure 15(b)) for fixedly adhering a support substrate in face-to-face relation through an adhesive layer 25 to the surface of the formed integrated circuit at the side opposed to said tentative substrate 20. Moreover, a fourth step is performed (as shown in Figure 15(c)) for removing said tentative substrate 20 to expose the flat insulating film 21 to the outside. Finally, a fifth step is performed for forming an electrode at least on the exposed flat surface of the insulating film.

Preferably at said first step, the semiconductor substrate made of single crystal silicon is thermally bonded at first to the tentative substrate of silicon through the insulating film of silicon dioxide. After this, said semiconductor substrate is polished and thinned to form the SOI substrate. For forming the insulating film, a silicon nitride film may be deposited at first as a surfacing treatment on the tentative silicon substrate, and then the silicon dioxide layer may be deposited by the CVD. This CVD silicon dioxide layer has excellent adhesion to the semiconductor substrate so that the semiconductor substrate can be thermally bonded in a fixed manner. The silicon nitride layer thus deposited as the surfacing treatment serve as an etching stopper at a later step. At the aforementioned

fourth step, the tentative substrate can be etched off by using the silicon nitride layer as the etching stopper. As a result, a flat insulating film is exposed to the outside.

The aforementioned third step is performed by fixedly adhering the support substrate in face-to-face relation to the surface of the semiconductor integrated circuit by using a fluid adhesive composed mainly of silicon dioxide, for example. Alternatively, much adhesive may be fed to the surface of the semiconductor integrated circuit and solidified to form the support substrate having a single-layer structure.

In the semiconductor device according to the present invention, transistor elements are integrally formed in the thin film laminated layer. This thin film laminated layer has its back formed with a wiring pattern for the transistor elements and its surface flattened and exposed to the outside. As a result, a variety of electrodes can be formed suitably and additionally according to the design specifications on the exposed flat surface. The so-called "double-side wiring" can be accomplished to densify the integration of the semiconductor device. The channel forming region of each transistor element is formed in the single crystal semiconductor thin film. Through this surface insulating film, there can be accomplished additional processes upon the single crystal semiconductor thin film. The so-called "double side treatment" can be accomplished to increase the degree of freedom for step designing of the semiconductor manufacture process. To the back of the thin film laminated layer, the support substrate is fixedly adhered in face-to-face relation through the adhesive film. As a result, the material for and the shape of the support substrate can be freely selected in accordance with the design specifications.

The semiconductor device having many such advantages can be manufactured by making use of the SOI substrate. First of all, the ordinary semiconductor manufacturing process is applied to the SOI substrate to form a group of thin film transistor elements. The support substrate is fixedly adhered in face-to-face relation by an adhesive to that surface of the SOI substrate, which is formed with such element group. After this, the tentative substrate portion of the SOI substrate is removed to expose the flat insulating film face to the outside. Thus, the grouped thin film transistor elements can be transferred from the SPI substrate to the support substrate to provide a semiconductor device which can be easily subjected to the double-sided treatment and wiring process.

By using the SOI substrate, like the case of the single crystal silicon wafer of the prior art, the LSI manufacturing technology can be utilized to form remarkably fine thin film transistor elements. The SOI substrate is structured, as has been described hereinbefore, such that the single crystal semiconductor thin film made of silicon is laminated on the tentative sub-

strate through the insulating film. This single crystal semiconductor thin film is superior in physical characteristics to the polycrystalline silicon thin film or the amorphous silicon thin film so that it is suited for the LSI manufacture. Since the polycrystalline silicon thin film, if used, has a crystal particle size of several μm , it necessarily restricts the fine structure of the thin film transistor elements. In addition, the polycrystalline silicon thin film has a film forming temperature of about 600°C and makes it difficult to exploit the miniaturizing technology or LSI manufacture technology requiring a high-temperature process of $1,000^{\circ}\text{C}$ or more. On the other hand, the amorphous silicon thin film has, if used, a film forming temperature of about 300°C and makes it impossible to use a high-temperature treatment required from the LSI manufacture technology. On the contrary, the single crystal semiconductor thin film is excellent in crystal uniformity and thermally stable so that it can be freely treated at a high temperature to form fine single crystal thin film transistor elements. Since, moreover, the single crystal silicon thin film has a higher charge mobility than the polycrystalline silicon thin film or amorphous silicon thin film, it is possible to provide transistor elements which are excellent in high-speed responsiveness.

Next, a first preferred embodiment of the present invention will be described in detail in the following. Figure 3 shows the embodiment, in which an integrated circuit wiring and an externally connecting pad electrode are separately formed on the upper and lower two faces. As shown, the thin film laminated layer 1 is formed with each of an insulated gate field effect transistor elements. This transistor element has its channel forming region 5, source region 6 and drain region 7 formed in the common single crystal silicon thin film 4. This single crystal silicon thin film 4 is covered with the surface insulating film 3 having a flat face. Below the channel forming region 5, there is arranged through the gate oxide film 8 the gate electrode 9. Below this gate electrode 9, there is formed the back layer film 10. This back layer film 10 is made of an inter-layer insulating film for covering and protecting the gate electrode 9. Moreover, the field insulating film 13 is formed to surround the transistor element. The back layer film 10 is formed with contact holes, through which are formed the source electrode 11 connected with the source region 6 and the drain electrode 12 connected with the drain region 7. The source electrode 11 and drain electrode 12 are wired in accordance with a predetermined pattern to connect the individual transistor elements along one face of the back layer film 10. To one face of the back layer film 10, there is fixedly adhered in face-to-face relation through the adhesive film 14 the support substrate 15 which supports the thin film laminated layer 1.

The thin film laminated layer 1 is partially formed with a through hole 16. This through hole 16 can be

formed by etching the field insulated film 13 selectively. The surface insulating film 3 is formed thereover with a pad electrode 17 for connecting the drain electrode 12 electrically through the through hole 16. The pad electrode 17 is provided for electric connection between the semiconductor device and an external circuit and is wire-bonded, for example. For this purpose, the pad electrode is given a size of about $100\mu\text{m}$ square far larger than that of the transistor element. Thus, the pad electrode occupying an especially large area is separated from the back wiring of the integrated circuit and formed on the surface so that the area of the back can be effectively exploited. Moreover, the pad electrode can be firmly formed by vacuum-evaporating metal aluminium over the surface insulating film 3 which is remarkably excellent in flatness. As a result, it is possible to perform a highly reliable wiring bonding.

Figure 4(a) shows a second embodiment of the semiconductor device according to the present invention. The same components as those of the embodiment shown in Figure 3 are designated by the identical reference numerals so that they can be easily understood. In the present embodiment, an additional gate electrode 18 is added to the gate electrode 9 which is formed previously. The additional gate electrode 18 is patterned over the surface insulating film 3 in alignment with the channel forming region 5 which is formed in the single crystal silicon thin film 4. As a result, the channel forming region 5 has its conductivity controlled downwardly and upwardly by the paired gate electrodes 9 and 18. With this structure, the transistor element has its threshold voltage determined substantially only by the material characteristics of the single crystal silicon thin film 4 but hardly by the influences of other size or shape factors so that the dispersion of electro-characteristics is reduced. By controlling the conductivity of the channel forming region simultaneously upwardly and downwardly, moreover, the ON/OFF characteristics of the transistor element can be remarkably improved to establish a high current. Unlike the prior art in which the gate electrode is formed only at one side, the back channel can be effectively prevented to improve the transistor characteristics. Accordingly, the channel length of the channel forming region can be miniaturized to an order of sub-micron, as compared with the prior art.

In the present invention, after the thin film transistor elements have been formed by using the SOI substrate, they are transferred to the support substrate 15 to provide the semiconductor device. As a result of this transfer, unlike the prior art, the gate electrode 9 is positioned below the channel forming region 5, which has its upper side opened for an additional processing. Thanks to this structure, the additional gate electrode 18 can be remarkably easily formed.

As has been described hereinbefore, the present

invention uses the SOI substrate to form the transistor elements for the single crystal silicon thin film. The single crystal silicon thin film is superior in miniaturization and high-speed responsiveness to the polycrystalline silicon thin film or the amorphous silicon thin film but is defective in that a higher optical leakage current will flow into the channel forming region. This optical leakage current increases the offset current of the transistor elements thereby to deteriorate the ON/OFF characteristics. In order to prevent establishment of that optical leakage current, the additional gate electrode 18 may preferably be exemplified by a shielding film having shielding characteristics. For example, after the metal aluminium has been deposited all over the flat face of the surface insulating film 3, a predetermined patterning is performed to form the additional gate electrode 18 so that an effective shielding film can be formed.

Figure 4(b) shows a third embodiment of the semiconductor device according to the present invention. The same components as those of the embodiment shown in Figure 1 are designated by the identical reference numerals so that they can be easily understood. In the present embodiment, a support substrate 15 is transparent by contrast with the second embodiment shown in Figure 4(a) wherein a light shielding layer is formed on an insulating film 3 with an opaque support substrate 15. In the present instance light scattered from the surface of the support substrate 15 may reach to the gate electrode 9 from the underside direction.

It is preferable for stable operation of a transistor element on a single crystal semiconductive layer that a gate electrode 9 contacted with a gate oxide layer 8 is made out of a polycrystalline layer. A polycrystalline thin film layer has characteristics of light transparency so that a light shielding layer 20 has to be formed on the gate electrode 9 to prevent a light from the underside of the gate electrode 9. The materials used for the light shielding layer 20 may be Cr, Ta, W and other metals. In the case of an electric conductive thin film used for the light shielding layer 20, the light shielding layer has a function the same as a gate electrode. The materials used for the light shielding layer 20 can be semiconductive or insulative materials such as a silicon germanium, nitride or others.

Figure 5 shows a fourth embodiment of the semiconductor device according to the present invention. Likewise, the same components as those of the preceding embodiments are designated by the identical reference numerals so that the present embodiment may be easily understood. The present embodiment relates to the semiconductor device having the so-called "DRAM structure". As shown, an opposed electrode 19 is patterned and formed over the surface insulating film 3 such that it is opposed to the drain region 7 of each transistor element formed in the single crystal silicon thin film 4. Between the drain reg-

ion 7 and the opposed electrode 19, there is interposed a dielectric layer which is made of the surface insulating film 3 to constitute a capacity element. In other words, the data storing capacity elements are coupled to the individual integrated transistor elements to form a DRAM. According to the present invention, this DRAM can be easily produced by patterning the opposed electrodes simply with respect to the flat face of the surface insulating film 3. After a voltage has been applied to the gate electrode 9 to render the channel forming region 5 conductive, charge is fed from the source region 6 to the drain region 7 to render the channel forming region 5 non-conductive. As a result, the supplied charge is temporarily stored as the stored data in the capacity elements. In this way, the data are written. In order to read out the written data, the channel forming region 5 may be rendered conductive again so that the charge once stored may be introduced into the source region 6 to have its quantity detected.

Figure 6 shows a fifth embodiment of the semiconductor device according to the present invention. In the present embodiment, the terminal electrode of the transistor element, i.e. one of the source electrode and the drain electrode is formed not on the back but on the surface. Thus, the wiring density on each face can be improved by dividing the wiring of the transistor element vertically of the thin film laminated layer 1. In case only one face is formed with the source electrode and the drain electrode, as in the prior art, the miniaturization of the transistor elements is impeded. In the present embodiment, the wiring line of the source electrode 11 is guided to the back, whereas a drain electrode 31 is formed on the surface through a contact hole 32 which is opened in the surface insulating film 3. As has been described above, the semiconductor device according to the present invention is provided by transferring the thin film transistor element from the SOI substrate to the support substrate so that the drain region 7 formed in the single crystal silicon thin film 4 is positioned on the surface through the surface insulating film 3. As a result, the electrode connection can be easily established through the surface insulating film 3. Thus, the double-face bonding of the integrated circuit can be accomplished to increase the capacity more than the prior art.

Figure 7 shows a sixth embodiment of the semiconductor device according to the present invention. Unlike the foregoing embodiments, the present embodiment uses a support layer 42 having a single-layer structure. This support layer 42 can be moulded by feeding and solidifying much adhesive to the back of the thin film laminated layer 1, which is formed with the semiconductor integrated circuit. Since, unlike the foregoing embodiments, the present embodiment need not use a separate support substrate, it is possible to reduce the production cost and to reduce the overall thickness of the semiconductor device. Since

the semiconductor device having such structure is formed into a sheet, it is suitably packaged in an IC card, for example.

Figure 8 is a section showing a portion of a seventh embodiment of the semiconductor device according to the present invention. Figure 8 is inverted upside-down from the foregoing Figures so that the present embodiment can be easily understood. Moreover, Figure 8 shows the state of a half-product so that the present embodiment may be easily understood. In the half-product state, as shown, an SOI substrate 51 is left. This SOI substrate 51 is composed of the thin film laminated layer 1 formed with the grouped transistor elements and a tentative substrate 52 supporting thin film laminated layer 1 temporarily through the insulating film 3. On the tentative substrate 52, there is deposited through the insulating film 3 the single crystal silicon thin film 4. This single crystal silicon thin film is formed with the channel forming region 5, the source region 6 and the drain region 7 of each transistor element. On the SOI substrate 51 formed integrally with the grouped transistor elements, there is fixedly adhered in face-to-face relation through the adhesive layer 14 the support substrate 15. This support substrate 15 is formed in advance with through holes 53 at a predetermined pitch. These through holes 53 are provided for releasing the gas which is produced during the heat treatment of the adhesive film 14. Without such through holes, the gas produced in the course of thermally setting the adhesive film 14 would have no way of escape to make it difficult to adhere the uniform and rigid support substrate 15 fixedly in the face-to-face relation. If the produced gas is confined in the adhesive film 14 to form bubbles, it deteriorates the reliability of the semiconductor device. In order to eliminate this disadvantage, therefore, the degasifying through holes 53 are formed in advance in the support substrate 15 in accordance with the present embodiment. After the support substrate has been fixedly adhered in the face-to-face relation by using the adhesive film 14, the tentative substrate 52 composing the SOI substrate 51 is polished and etched off to expose the flat insulating film 3 to the outside.

Figure 9 is a section showing a portion of an eighth embodiment of the semiconductor device according to the present invention. The present embodiment relates to the so-called "MROM structure". In this MROM, i.e. mask ROM, the data are written in the individual channel forming regions of the transistor elements which are integrally formed in an array shape. The data are written by setting the conductivity of the channel forming region selectively. In the present invention, as shown, after the transistor elements have been integrally formed over the SOI substrate, the semiconductor device is transferred to the support substrate 15. Unlike the semiconductor device of the prior art, therefore, the gate electrode 9

is laid under the channel forming region 5 formed in the single crystal silicon thin film 4. The channel forming region 5 has its upper face opened. With such structure, the conductivity of the channel forming region 5 can be selectively set and controlled from the surface side. Specifically, a resist film 60 is patterned over the surface insulating film 3 in accordance with the data pattern to be stored. As a result, the element regions of the individual transistor elements are selectively masked. If the surface of the semiconductor device is implanted with ions all over its surface, only the element regions unmasked are selectively doped with the impurity ions to increase the conductivity of the channel forming region 5. Thus, the data are written in the transistor element array. For reading out the data, a potential difference to be established between the source electrode 11 and the drain electrode 12 may be detected by applying a predetermined voltage to the gate electrode 9.

According to the present invention, the data writing operation is carried out at the final stage of the semiconductor device manufacturing process. This makes it possible to manufacture a great number of half-products in advance before they are written with the data. A remarkably efficient manufacture control can be accomplished by finally writing the data according to the specifications required.

Figure 10 is a schematic section showing a portion of a ninth embodiment of the semiconductor device according to the present invention. The present embodiment relates to a semiconductor device to be used as a light valve substrate. A light valve substrate 71 made of the semiconductor device is composed, as shown, of the thin film laminated layer 1 formed integrally with the grouped transistor elements, the transparent support substrate 15, and the adhesive film 14 for adhering the former two fixedly in the face-to-face relation. Each transistor element is made of an insulated gate field effect transistor and is composed of the channel forming region 5, the source region 6, the drain region 7, and the gate electrode arranged below the channel forming region 5 through the gate oxide film 8. The surface insulating film 3 is arranged to cover the single crystal silicon thin film 4. The surface insulating film 3 has a remarkably flat surface. This flat surface is arranged with transparent electrodes 72 for constituting pixels in a manner to correspond to the individual transistor elements. Each transparent electrode 72 is electrically connected with the drain region of the corresponding transistor element through a contact hole 73 opened in the surface insulating film 3. The transistor element functions, as a switch for the transparent electrode 72, not only to apply a predetermined voltage to the gate electrode 9 to render the channel forming region 5 conductive but also to apply a predetermined drive voltage to the source electrode 11 to drive the transparent electrode 72. This transparent electrode 72 is formed over the

remarkably flat surface insulating film 3 so that it has excellent smoothness and dimensional accuracy. The transparent electrode 72 and the thin film laminated layer 1 formed with a corresponding transistor element or switching element are supported by the transparent support substrate 15 through the adhesive film 14. In case the semiconductor device is used as the light valve device, it has to be optically transparent so that it may control the transparency of an incident light. In the present embodiment, therefore, the support substrate 15 is made of a transparent material such as glass, and the adhesive film 14 is also made of a transparent material. Accordingly, the laminated structure composed of the transparent electrode 72, the adhesive film 14 and the transparent support substrate 15 is transparent as a whole so that it can achieve the light valve function for each pixel.

An opposed substrate 74 is arranged at a predetermined gap and opposite to the light valve substrate 71 having such structure. The opposed substrate 74 is made of a glass material and has its inner surface formed with a common electrode 75. The gap between the light valve substrate 71 and the opposed substrate 74 is filled up with an electro-optical substance such as a liquid crystal layer 76 for modulating an incident light optically for each pixel. Specifically, the transparency to the incident light is varied to effect the light valve function in accordance with the level of the drive voltage which is applied between the transparent electrode 72 forming the pixel and the common electrode 75. In case the liquid crystal layer 76 is used as the electro-optical substance layer, its thickness has to be controlled to a remarkably uniform thickness so that a uniform light valve function may be achieved. Since, in this case, the surface insulating film 3 positioned in the uppermost portion of the light valve substrate 71 has a remarkably flat face, it is easy to attain a uniform thickness. In addition, an orientation is required in case the liquid crystal layer 76 is used. This orientation can be uniform because the light valve substrate 71 has an excellently smooth surface.

Next, the process for manufacturing a semiconductor device according to a tenth embodiment of the present invention will be described in detail in the following with reference to Figures 11 to 14. Figure 11 is a process diagram, showing a first step of the semiconductor device manufacturing process. At this step, an SOI substrate 81 is prepared at first. This SOI substrate 81 has the single crystal semiconductor thin film 4 which is laminated on a tentative substrate 82 through the insulating film 3.

The SOI substrate 81 having such structure can be prepared by depositing a polycrystalline silicon thin film on the surface of the tentative substrate 82 made of an insulating or semiconductor substance by the chemical vapour growth, and subsequently by heating it with the laser beam irradiation so that the polycrys-

talline film may be recrystallized into a single crystal structure. Generally speaking, however, the single crystal obtained by the recrystallization of a polycrystal does not always have a uniform crystal orientation but has a relatively high lattice defect density. For these reasons, the application of the miniaturizing technology or the LSI manufacture technology as in the silicon wafer to the SOI substrate prepared by the recrystallization method is restricted to some extent. In the present embodiment, therefore the single crystal silicon thin film 4 having a uniform crystal orientation and a lattice defect of low density like those of the silicon wafer used widely in the semiconductor manufacture process is formed over the tentative substrate 82. This method will be specifically described in the following.

First of all, the single crystal silicon plate and the tentative substrate 82 are prepared. This tentative substrate 82 is made of a silicon material, for example. On the other hand, the single crystal silicon plate may be exemplified by a high quality silicon wafer used in the LSI manufacture, for example, and has a crystal orientation of a uniformity in a range of $(100) 0.0 \pm 1.0$ and a single crystal lattice defect density of $500/\text{cm}^2$ or less. This single crystal silicon plate has its back flattened. On the other hand, the surface of the tentative substrate 82 is formed with the insulating film 3. This insulating film 3 is prepared by depositing silicon dioxide by the chemical vapour growth or CVD, for example. Incidentally, a silicon nitride layer may preferably be deposited as the surfacing treatment on the surface of the tentative substrate 82 before the silicon dioxide layer is deposited by the CVD. The insulating film 3 thus deposited also has a flat face.

Next, the single crystal silicon plate having the flat face and the tentative substrate 82 are thermally bonded by superposing and heating them through the insulating film 3. At this time, those two plate members are thermally bonded through the excellently adhesive insulating film 3 made of silicon dioxide so that they are fixedly bonded to each other.

Subsequently, the surface of the single crystal silicon plate is polished. As a result, the insulating film 3 is formed thereover with the single crystal silicon thin film 4 which is polished to a desired thickness. Thus, as shown in Figure 11, there is obtained the SOI substrate 81 which is composed of the tentative substrate 82 of silicon and the single crystal silicon thin film 4. Incidentally, the polishing treatment for thinning the single crystal silicon plate may be replaced by the etching treatment. Since the single crystal silicon thin film 4 thus obtained retains the quality of the silicon wafer substantially as it is, it is possible to obtain a semiconductor substrate material which is extremely excellent in the uniformity of the crystal orientation and the density of the lattice defect.

Next, a second step of the semiconductor device

manufacturing process according to the present invention will be described in the following with reference to Figure 12. At this step, the single crystal silicon thin film 4 is formed with the semiconductor integrated circuit to form the thin film laminated layer 1. Specifically, the single crystal silicon thin film 4 is selectively thermally oxidized at first so that it is converted into the field insulating layer 13 while leaving individual element regions. As a result, the element regions are shaped such that they are surrounded by the field insulating layer 13. Subsequently, the element region surface is thermally oxidized to form the gate insulating film 8. An intermediate electrode film is deposited on the gate insulating film 8 and is subjected to a predetermined patterning to form the gate electrode 9.

In a case of the third embodiment of the present invention shown in figure 4(b), the intermediate electrode film has a stacked structure comprising a gate electrode and a light shielding layer. In this case, the intermediate electrode film having both a gate electrode film and a light shielding film are processed as a gate electrode 9 after this step. Then, the gate electrode 9 is used as a mask to dope the single crystal silicon thin film 4 with an impurity to form the source region 6 and the drain region 7 by the ion implantation. As a result, the source region 6 and the drain region 7 are formed in self-alignment with the gate electrode 9. The channel forming region 5 left undoped is formed between the doped source region 6 and drain region 7. After the end of the ion implantation, the element regions are covered all over the surface with the passivation film 10. Then, the contact hole is opened in the passivation film 10 to form the source electrode to be connected with the source region 6 and the drain electrode connected with the drain region 7. As a result, the passivation film 10 and the field insulating layer 13 have their surface wired with the integrated circuit composed of the grouped transistor elements. Simultaneously with this, the gate electrode 9 is also wired.

Next, a third step of the semiconductor device manufacturing process according to the present invention will be described in the following with reference to Figure 13. At this third step, a support substrate is fixedly adhered in a face-to-face relation to the opposite side of the tentative substrate 82. For this, an adhesive is applied at first to the surface of the thin film laminated layer 1 formed with the semiconductor integrated circuit, to form the adhesive layer 14. A material to be used for the adhesive can be exemplified by a polyimide resin or an epoxy resin. The polyimide resin is excellent in heat resistance and in little content of an impurity. On the other hand, the epoxy resin is excellent in workability and in intense adhesion. Nevertheless, those organic materials have very different coefficients of linear expansion than that of the silicon material and may raise a prob-

lem in reliability in dependence upon the intended use of the semiconductor device. Moreover, those organic materials necessarily contain alkali ions and may exert adverse effects upon the reliability of the semiconductor device. In the present embodiment, therefore, the adhesive used in a fluid inorganic material having a composition, in which silicon dioxide particle is dispersed in a solvent. Such silicon dioxide adhesive can be subjected to a heat treatment to form a denser silicon dioxide film. This silicon dioxide film not only is excellent in reliability, because it contains few alkali ions, but also can reduce the thermal stress because its coefficient of linear expansion is as high as that of the substrate material. The silicon dioxide adhesive can be applied to the surface of the integrated circuit by a simple method such as the spinner, dipping or spraying method. Thanks to the fluidicity, the silicon dioxide adhesive is excellent in step smoothness.

At a step shown in Figure 14, moreover, the support substrate 15 is adhered to the surface of the applied adhesive film 14. The material for the support substrate 15 can be suitably selected in accordance with the using object of the semiconductor device. For example, silicon or quartz is selected as the material. By the heat treatment in this state, the solvent contained in the adhesive film 14 is evaporated away, and the fusion of the silicon dioxide particle advances until the support substrate 15 and the SOI substrate 81 are rigidly adhered to each other in the face-to-face relation. The adhesive film 14 thus heated forms a dense silicon dioxide film having a quality substantially identical to that of a thermally oxidized film. Incidentally, the solvent contained in the adhesive is inorganic or organic. The organic solvent is suited for the case, in which an especially thick adhesive film is to be formed. If this thickness is increased to a considerable extent, the support substrate can be constructed of the adhesive film itself. In this case, the completed semiconductor device takes a sheet shape and can be applied to an especially thin device.

Finally, with the support substrate 15 and the SOI substrate 81 being adhered, the tentative substrate 82 is removed to expose the insulating film 3 having the flat face to the outside. This removal is carried out by etching the tentative substrate 82 of silicon, for example. At this time, the interface between the insulating film 3 and the tentative substrate 82 is formed as the surfacing treatment with a silicon nitride layer so that the silicon nitride layer effectively functions as the etching stopper. Specifically, due to the difference in the etching rate between the silicon and the silicon nitride, the etching removal of the tentative substrate 82 of silicon substantially ends at the step reaching the silicon nitride film. Thus, the semiconductor device shown in Figure 1 can be finally obtained. Incidentally, the arrangement shown in Figure 14 is inverted upside-down from that shown in Fig-

ure 1 so that it may be easily understood. The exposed insulating film 3 has a remarkably excellent flatness and is arranged therebelow with the single crystal silicon thin film 4. As a result, this flat surface insulating film 3 can be easily subjected to a variety of additional treatments including at least the formation of electrodes, and the single crystal silicon thin film 4 can also be easily subjected, if desired, to an additional treatment.

As has been described hereinbefore, according to the present invention, the integrated circuit formed on the SOI substrate is transferred to the support substrate, and the tentative substrate portion of the SOI substrate is then removed so that the semiconductor device has its one face wired in advance and its other face exposed to the outside. This exposed face has a flat surface and is arranged just therebelow with the single crystal semiconductor thin film. Since the exposed face can be subjected to the additional treatment of forming electrodes or wiring, the semiconductor device according to the present invention can be given the double-side wiring structure to raise an effect that its packaging density is improved far better than the prior art. By dividing the wiring lines of the integrated circuit into upper and lower faces, the wiring density can be substantially doubled to miniaturize the integrated circuit. Alternatively, the thin film laminated layer formed with the integrated circuit is formed on its back with a wiring pattern and on its surface with an externally connecting pad electrode, thus raising an effect that the surface and back can be efficiently exploited. Another effect is that the semiconductor device satisfying various applications can be remarkably easily manufactured by adding various electrodes to the exposed surface of the semiconductor device in accordance with the design specifications. For example, the semiconductor device substrate for driving the light valve is obtained by forming a transparent electrode for defining the pixel, for example. Moreover, the DRAM can be easily manufactured by forming a capacity electrode. By forming an additional gate electrode, furthermore, it is possible to manufacture a semiconductor device which is composed of transistor elements having an excellent ON/OFF ratio. In addition, a semiconductor device composed of transistor elements having a low offset current can be manufactured by making the added gate electrode of a shielding material.

In the structure of the semiconductor device according to the present invention, the single crystal semiconductor thin film is arranged just below the surface insulating film. As a result, an additional treatment can be applied through the surface insulating film to raise an effect that the so-called "double-sided processing" can be accomplished. For example, an MROM can be manufactured remarkably easily by doping the channel forming region of the transistor element selectively through the surface insulating

film.

According to the present invention, the thin film laminated layer formed with the semiconductor integrated circuit is supported through the adhesive film by the support substrate. As a result, no integral and undividable relation resides unlike the prior art between the thin film laminated layer and its support substrate, thus raising an effect that the material for the support substrate can be suitably selected in accordance with the use or the like of the semiconductor device. In case the semiconductor device is used as the light valve driving substrate, for example, a transparent material such as quartz can be selected as the material for the support substrate. Alternatively, in case the semiconductor device is packaged in an IC card or the like, the sheet-shaped semiconductor device can be easily manufactured by increasing the thickness itself of the adhesive film to form the support substrate.

According to the present invention, a semiconductor device to be subjected to the double-side processing and wiring is manufactured by using transfer technology. As a result, there can be attained an effect that a semiconductor device of high performance and density can be obtained without any complicated processing. Especially, an effect that the ordinary LSI manufacturing technology can be sufficiently exploited can be obtained by applying the ordinary LSI manufacturing technology to the SOI substrate to form an integrated circuit and by transferring the integrated circuit to the support substrate. By thermally bonding and polishing a silicon wafer to form the single crystal semiconductor thin film on the surface of the SOI substrate, there is attained an effect that the semiconductor device can be manufactured by using a substrate material which is excellent in the uniformity of crystal orientation and in the density of the lattice defect.

Figure 16 is a top plan view showing a semiconductor device for a light valve device according to an eleventh embodiment of the present invention. Reference numeral 111 designates an insulating transparent thin film, which is arranged on its upper face with a plurality of pixel electrodes 113 in a matrix shape. The insulating transparent thin film is further formed, at its portions except the pixel electrodes 113, with a semiconductor single crystal thin film, which is formed with switch elements 114 adjacent to the individual pixel electrodes 113.

On the other hand, the grouped pixel electrodes 113 are surrounded by an X driver 131, a Y driver 132, a pad lead-out portion 125 and a wiring pattern 120 for connecting the foregoing elements. The switch element 114 is a field effect transistor, which has its drain electrode connected with a corresponding pixel electrode 113, its gate electrode connected with a scanning line 129, its source electrode connected with a signal line 130. Moreover, the scanning line 129 is

connected with the Y driver 132, and the signal line 130 is connected with the X driver 131. These individual drivers are connected through the pad lead-out portion 125 with a not shown external circuit. The pad lead-out portion 125 extends, as will be described with reference to Figure 17, to the lower face of the insulating transparent thin film, to which its surface is exposed.

At the uppermost portion of the thin film substrate thus far described, there is disposed a polarizing plate, which is omitted for convenient description.

Figure 17 is a section taken along line A - A' of Figure 16 and showing the relations among the X driver 131, the wiring pattern 120, the shielding film and the pad lead-out portion 125. This pad lead-out portion 125 extends, as apparent from Figure 17, through the insulating transparent thin film 111 from the upper to lower faces thereof and further from the lower portion to the outside while avoiding the pixel electrode portion. With the pad lead-out portion 125, there is connected an external signal line, through which signals are transferred to the individual drivers 131 and 132. The X driver 131 and the wiring pattern 120 are enclosed by an electric insulating passivation film 119, onto which a transparent electric insulating substrate 123 is fixed through an adhesive. A polarizing plate 133 is placed on the transparent electric insulating substrate 123. The pad lead-out portion 125 has its surface exposed through the lower face of the insulating transparent thin film 111 to the outside, and a shielding film 124 is placed in a position opposite to the X driver 131.

Figure 18 is a section showing an embodiment, in which a light valve device is made of the semiconductor device of Figure 17. An opposite substrate is disposed below the lower face of the insulating transparent thin film of Figure 18 and in a position opposite to the grouped pixel electrodes at a gap. This gap is filled up with a liquid crystal 127 and has its sides sealed up with a resin 135. On the other hand, the aforementioned opposite substrate is composed of an orientation film 126, an equi-potential electrode 136 and a glass substrate 128.

This light valve device is cut along line B-B' of Figure 16, but the pixel electrode 113 is shown, for convenient description, in a reduced smaller scale than that of the switch element 114.

The pixel electrodes are formed by preparing a substrate, in which a single crystal thin film semiconductor layer is thermally bonded to the upper face of the insulating transparent thin film 111, by etching off a portion of the single crystal thin film semiconductor layer in a predetermined shape to expose it to the surface of the underlying insulating transparent thin film 111, and by forming the plural electrodes 113 in a matrix shape on the exposed surface. This means may be a generally used one.

The switch element forms, on a single crystal thin

film semiconductor layer 112, an insulated gate field effect transistor which is composed of a gate electrode 115 and a pair of impurity-diffused regions, i.e. a source electrode 116 and a drain electrode 117. The drain electrode 117 is connected with the corresponding pixel electrode 113, and the gate electrode 115 is arranged over the channel forming region of the switch element 114 through an insulating film 118. over the switch elements 114, there is formed through the insulating film 119 the wiring pattern 120 which is made of aluminium. This wiring pattern 120 is electrically connected with the source electrodes 116 of the switch elements 114 through contact holes formed in the insulating film 119 and further with the pad lead-out portion 125, as shown in Figure 17. The wiring pattern 120 is formed on its surface with the passivation film 121, on which the transparent electric insulating substrate 123 is placed through the adhesive layer so that it may be prevented from being damaged due to a mechanical stress. The polarizing plate 133 is placed on the insulating substrate 123, as has been described with reference to Figure 17.

Across the insulating transparent thin film 111, the shielding film 124 is formed below the switch elements 114 and the Y driver 132 to prevent any undesired operation by a light. The external signal is inputted from the not-shown pad lead-out portion so that the liquid crystal panel is accomplished. Specifically, the gate electrodes 115 of the individual switch elements are connected with the scanning line 120 (as shown in Figure 16) so that they are fed with scanning line signals by the Y driver 132 to control the ON/OFF of the individual switch elements in a linear order. Specifically, the image signals outputted from the X driver 131 are fed to the image electrodes 113 through the switch elements 114 which have their conductive states selected through the signal lines 130. As a result, the charges according to the magnitudes of the image signals are fed to and stored in the individual image electrodes 113. The liquid crystal layer 127 is excited by the stored charges so that it has its transparency changed to perform the light valve function. The switch elements 114 are non-conductive, when unselected, so that the image signals written before are latched in the image electrodes 113.

Since the switch elements 114 are shielded by the shielding film 124, no optical leakage current is generated while the switch elements 114 are OFF, so that the charges stored in the pixel electrodes 113 will not leak. As a result, a stable light valve function is exhibited.

Since, moreover, the switch elements 114 are formed in the silicon single crystal thin film 112 having a remarkably high charge mobility, it is possible to construct a light valve device which has a high speed signal responsiveness. Furthermore, the circuit including the X driver 131 and the Y driver 132 can be formed

on the common silicon thin film simultaneously with the switch elements 114, thus raising an effect that the manufacture process is simplified. Incidentally, the present embodiment has been described in connection with the light valve device formed with the polarizing plate 133. Nevertheless, the polarizing plate need not be formed if the liquid crystal used is exemplified by a polymer-dispersed liquid crystal, in which a liquid crystal is dispersed in a high-molecular material.

Figures 19(a) to 19(g) show a twelfth embodiment of a process for fabricating a semiconductor device for a light valve device according to the present invention. First of all, a substrate shown in Figure 19(a) is prepared. This substrate is formed by adhering the silicon single crystal thin film 112 to a silicon substrate 151 through the silicon dioxide layer 111 which is made of the insulating transparent thin film. The silicon substrate 151 is used to hold the mechanical strength when the single crystal thin film 112 has its face processed.

Next, the silicon single crystal thin film 112 is removed at the positions corresponding to the pixel electrodes by the well-known method. Then, the remaining single crystal thin film is formed by the well-known method with the X driver 131, the Y driver 132 and the switch elements 114 and is removed to cover the exposed portion of the silicon dioxide layer 111 with the transparent conductive layer thereby to form the pixel electrodes 113 (as shown in Figure 19(b)). The not-shown passivation film and wiring pattern are formed over the pixel electrodes 113 thus formed and the drive elements 131, 132 and 114. Figure 19(b) shows the state thus established.

As shown in Figure 19(c), moreover, an adhesive layer 122 represented by silicon dioxide is applied to them and is overlain by the glass substrate 123 with the polarizing plate.

Next, this structure is inverted upside-down to place the silicon substrate 151 at the upper face, and this silicon substrate 151 is completely etched off to expose the silicon dioxide layer 111 to the outside. This state is shown in Figure 19(d). In this state, as shown in Figure 19(e), (a plurality of) through holes for the pad lead-out portion 125 are bored in the predetermined positions by the etching process. With the through holes being open, a metal such as aluminium is deposited all over the surface in a shieldable thickness. This state is shown in Figure 19(f).

This metal-deposited face 152 is patterned to remove the undesired portions corresponding to the pixel electrodes thereby to form the pad lead-out portion 125 and the shielding film 124 simultaneously. After this, an orientation layer is formed in the portions corresponding to the pixel portions. The completed state is shown in Figure 19(g).

Figure 20 is a detailed section for explaining the connection relation between the pad lead-out portion

125 and the wiring pattern 120. As shown, the pad lead-out portion 125 is connected through the silicon dioxide layer 111 from the upper to lower faces thereof with the wiring pattern 120 of the transistor constituting the driver 131 (or 132).

As has been described hereinbefore, according to the present embodiment, the orientation film for orienting the liquid crystal of said liquid crystal layer can be formed on the flat surface because the switch elements and the pixel electrodes are buried in the adhesive layer 122 and not exposed to the liquid crystal layer 127, even if the pixel electrodes and the switch elements have different thicknesses so that their undulations cannot be avoided. As a result, the display image of the light valve device, if formed, can be prevented from having a defect such as an irregular contrast.

Since, moreover, the pad lead-out portion 125 is exposed to the insulating transparent thin film at the side to be formed with the orientation film, no new space need be prepared for the pad lead-out portion 125, thus raising advantages that the size can be reduced and that the shielding layer and the pad lead-out portion 125 can be simultaneously formed.

Since, furthermore, the switch elements 114 are formed in the silicon single crystal thin film 112 having a remarkably high charge mobility, there can be attained an effect that it is possible to construct a light valve device having a high-speed signal responsiveness.

Figures 21(a) to 21(d) are explanatory diagrams showing a thirteenth embodiment according to the present invention.

Figure 21(a) is a top plan view showing a substrate 161 to be used in the present invention, and Figure 21(b) is a schematic section showing the structure of one chip manufactured from the substrate 161. As shown, this substrate 161 is formed into a wafer shape having a diameter of 6 inches, for example. The substrate 161 has a five-layer structure which is composed of a support layer 162 made of quartz, for example, a single crystal semiconductor layer 163 formed over the support layer 162 and made of silicon, for example, an adhesive layer 164 formed between the support layer 162 and the single crystal semiconductor layer 163 and made of an organic adhesive, glass having a low melting point or the like, an insulating layer 165 over the single crystal semiconductor layer 163, and a light shielding layer 166 formed over the insulating layer 165. In the substrate 161, the miniaturized semiconductor manufacturing technology is applied to the single crystal semiconductor layer 163 so that the driver circuit and the pixel electrode of an active matrix display system are formed for each chip section, for example.

Figure 21(c) is an enlarged top plan view showing an integrated circuit chip obtained from the substrate 161. As shown, the integrated circuit chip 167 has its

one side given a length of 1.5 cm, for example, so that it is far more miniaturized than that of the active matrix display system of the prior art. The integrated circuit chip 167 is composed of: a pixel region 168 which is formed with fine pixel electrodes arranged in a matrix shape and insulated gate field effect transistors corresponding to the individual pixel electrodes; an X driver region 169 for a driver circuit, i.e. the X driver for feeding the image signal to each transistor; and a scanning circuit, i.e. a Y driver region 170 for scanning the individual transistors in a linear sequence. Since the single crystal thin film having a far higher charge mobility and less crystal defects than those of the amorphous thin film or the polycrystalline thin film is used according to the present invention, the X and Y drivers requiring a high-speed responsiveness can be formed on a face shared with the pixel region.

Figure 21(d) is a section showing a microminiature and highly dense active matrix type light valve device which is assembled by using the aforementioned integrated circuit chip 167. As shown, the light valve device is composed of an opposed substrate 171 which is arranged opposite to the integrated circuit chip 167 at a predetermined gap, and a liquid crystal layer 172 filling up said gap and made of an electro-optical substance layer. Incidentally, the integrated circuit chip 167 has its surface covered with an orientation film 173 for orienting the liquid crystal molecules contained in the liquid crystal layer 172. The individual pixel electrodes formed in the pixel region 168 of the integrated circuit chip 167 are selectively excited, when the corresponding transistor elements are turned on, to act upon and control the optical transparency of the liquid crystal layer 172 so that they function as the light valve. Since the individual pixel electrodes have a size of about 10 μm , it is possible to provide a remarkably highly fine active matrix liquid crystal light valve device.

Figure 22(a) is a top plan view showing an A portion of the pixel region 168 of Figure 21(c) in an enlarged scale and shows one pixel. As shown, this pixel 174 is composed of a pixel electrode 175, a transistor 176 for exciting the pixel electrode in response to a signal, a signal line 177 for feeding the signal to said transistor 176, and a scanning line 178 for scanning said transistor. The signal line 177 is connected with the X driver, and the scanning line 178 is connected with the Y driver.

Figure 22(b) is a schematic section showing the same one pixel 174. The transistor 176 is composed of a drain region and a source region formed in the single crystal thin film layer 163, and a gate electrode 179 formed over the channel region through a gate insulating film. In short, the transistor 176 is of the insulated gate field effect type. The gate electrode 179 is formed of a portion of the scanning line 178, the pixel electrode 175 is connected with the drain region, and a source electrode 180 is connected with the

source region. This source electrode 180 forms part of the signal line 177. The shielding film 166 shields incident light from the transistor 176 to prevent the optical leakage current which might be established between the source region and drain region of the transistor 176. By holding the shielding film 166 at a constant potential, moreover, stray potential between the liquid crystal drive electrodes 175 of the adjacent pixels is blocked. Since, furthermore, the shielding film 166 and the liquid crystal drive electrode 175 have planarly overlapping portions through the insulating film 165, there can be established a capacitance for holding the voltage which is written in the pixel electrodes 165.

Figures 23(a) to 23(e) show a fourteenth embodiment of a process for manufacturing the semiconductor device, especially its pixel portion for the light valve device of the present invention.

As shown in Figure 23(a), the single crystal semiconductor layer 163 is formed over a single crystal semiconductor substrate 185 through the insulating film 165. Specifically, for example, the single crystal silicon substrate and the substrate silicon can be insulated with the silicon oxide, while leaving the single crystal silicon layer on the surface of the silicon substrate, by doping the silicon substrate with oxygen ions and then annealing it. According to another example, this insulating can be achieved by adhering the silicon single crystal substrate having the oxide film on its surface and the silicon single crystal substrate and by removing one silicon substrate up to the thickness of the thin film layer.

Next, as shown in Figure 23(b), the pixel electrodes 175, the driver circuit, the control circuit and so on are formed in the single crystal semiconductor layer 163 by the ordinary semiconductor miniaturization.

As shown in Figure 23(c), moreover, the single crystal semiconductor substrate 185 and the support layer 162 are adhered to each other through the adhesive layer 164. The support layer 162 is made of an insulator such as glass or quartz.

Figure 23(d) is a diagram showing the state, in which the semiconductor substrate is removed while leaving the insulating layer 165 and the single crystal semiconductor layer 163 of the single crystal semiconductor substrate 185. The removing method used is exemplified by the polishing or etching method. At this time, the insulating layer can be used as the etching stop layer or for detecting the final point of the polishing operation.

Finally, as shown in Figure 23(e), the optically sensitive element portion such as the transistor formed in the single crystal semiconductor layer 163 is covered with the light shielding layer 166 which is made of a metal film.

Figure 24 is a schematic exploded perspective view showing a fifteenth embodiment of the light valve

device according to the present invention. As shown, the light valve device is composed of the drive substrate 161, the opposite substrate 171 opposed to said drive substrate, and the liquid crystal layer 172 of an electro-optical substance layer arranged between said drive substrate 161 and said opposite substrate 171.

The drive substrate 161 is formed with pixel electrodes or drive electrodes for defining the pixels 175, and a driver circuit for exciting the drive electrodes in response to a predetermined signal. The drive substrate 161 is given a five-layer structure which is composed of the support layer 162 made of quartz, the single crystal silicon semiconductor film layer 163, the adhesive layer 164, the insulating layer 165 and the light shielding layer 166. In addition, a polarizing plate 181 is adhered to the back of the quartz carrier layer 162. Moreover, the driver is made of an integrated circuit which is formed in the single crystal silicon semiconductor film layer 163. This integrated circuit includes a plurality of field effect type insulated gate transistors 176 arranged in a matrix shape. The transistor 176 has its drain electrode connected with the corresponding pixel electrode 175, its gate electrode connected with the scanning line 178, and its source electrode connected with the signal line 177. Said integrated circuit further includes the X driver 169 and is connected with the arrayed signal lines 177.

The integrated circuit further includes the Y driver 170 and is connected with the arrayed scanning lines 178. The X driver 169 and Y driver 170 are connected with an image signal processor 186 which is also formed in the single crystal semiconductor film layer 163 so that they are driven through the processor 186 in response to the image signals coming from the outside. On the other hand, the opposite substrate 171 is composed of a glass substrate 182, a polarizing plate 183 formed on the outer face of the glass substrate 182, and an opposite or common electrode 184 formed on the inner face of the glass substrate 182. The light shielding layer 166 covers that portion such as the transistor or the PBN junction of the semiconductor film layer 163, which has its characteristics changed by the influence of a incident light, through the insulating layer 165.

Next, the operations of the aforementioned embodiment will be described in detail with reference to Figure 24. The individual transistor elements 176 have their gate electrodes connected with the scanning lines 178 so that they are fed with the scanning signals by the Y driver 170 to control their ON/OFF switching in a linear sequence. The display signal outputted from the X driver 169 is fed through the signal line 177 to the selected transistor 176 in the conductive state. The display signal thus fed is transmitted to the corresponding pixel electrode 175 so that it excites the pixel electrode and acts upon the liquid crystal layer 172 to establish a transparency of sub-

stantially 100%.

At an unselected time, on the other hand, the transistor elements 176 are turned off to hold the display signals written in the pixel electrodes as the charges. Incidentally, the liquid crystal layer 172 has a high specific resistance and normally operates as a capacity. The ON/OFF current ratio is used to express the switching performances of those drive transistor elements 176. The current ratio necessary for the liquid crystal operation is easily determined from the write time and the latch time. In case the display signals are TV signals, for example, 90% or more of the display signals for one scanning period of about 60 μ sec have to be written.

On the other hand, 90% or more of the charges have to be latched for one field period of about 16 msec. As a result, the current ratio required has five figures or more. Since, at this time, the drive transistor elements are formed over the single crystal silicon semiconductor thin film layer 163 having a remarkably high charge mobility, six or more figures of the ON/OFF ratio can be retained. Thus, it is possible to provide an active matrix type light valve device having a remarkably high-speed signal responsiveness. By making use of the high mobility of the single crystal thin film, moreover, especially the peripheral circuits 169 and 170 can be formed over the common silicon single crystal semiconductor thin film. Since, moreover, the light shielding layer 166 is formed, the light valve device can operate without being influenced by intense incident light.

As has been described hereinbefore, according to the present invention, the light valve device is formed by using the integrated circuit chip substrate which is obtained by forming the pixel electrodes and the driver circuits integrally in the semiconductor single crystal thin film formed over the carrier layer by using the semiconductor miniaturizing technology. As a result, there can be attained an effect that it is possible to provide a light valve device having a remarkably high pixel density. Since the integrated circuit technology can be used for the single crystal thin film layer, there can be attained an effect that it is possible to easily add the circuit having various functions equivalent to those of the LSI. A further effect is that not only the switching transistors and the driver circuits can be simultaneously built in by using the single crystal thin film. Even with an intense incident light, furthermore, a normal operation can be attained by the shielding film. Furthermore, there can be attained a remarkable effect that the image quality of the light valve device can be highly improved for preventing the crosstalk between the pixels by establishing a capacity between the shielding film and the pixel electrodes, by elongating the latch time of the signals written in the pixels, and by shielding the electric field between the pixels.

Figures 25(a) and 25(b) show a sixteenth embodi-

diment of the light valve device using a semiconductor device according to the present invention and are diagrams for explaining the sectional structure of the light valve device. In the present embodiment, the thin semiconductor film over the thin insulating film, from which the support substrate of the semiconductor device, is used as one substrate of the light valve device.

Figure 25(a) is a section showing the light valve device. A substrate 191 is made of a thin film which is composed of a single crystal semiconductor thin film 193, an insulating film 195, and a light shielding film 196 formed over the insulating film 195. Between said substrate 191 and a support substrate 192 formed with a transparent electrode 197, there is formed an electro-optical substance layer 194. This electro-optical material layer 194 to be used can be exemplified by a liquid crystal or a polymer liquid crystal, in which a liquid crystal is dispersed in a polymer material. The single crystal semiconductor thin film 193 is formed thereover for the individual sections with the driver circuits and the pixel electrodes of an active matrix display system by applying the miniature semiconductor manufacturing technology.

Figure 25(b) is a schematic section showing one pixel. As shown, a pixel 204 is composed of a pixel electrode 205, a transistor 106 for exciting the pixel electrode in response to a signal, a signal line for feeding the signal to said transistor 206, and a scanning line for scanning said transistor, although the latter two components are not shown. On the other hand, the signal line is connected with the X driver, and the scanning line is connected with the Y driver. The transistor 206 is composed of a source region 211 and a drain region 212 formed in the single crystal thin film layer 193, and a gate electrode 209 formed over the channel region through the gate insulating film. In short, the transistor 206 is of the insulated gate field effect type. The gate electrode 209 is formed of a portion of the scanning line, and the pixel electrode 204 is connected with the drain region 212 whereas a source electrode 210 is connected with the source region 211. The source electrode 210 forms part of the signal line. The light shielding film 196 shields incident light coming to the transistor 206 to prevent an optical leakage current which is established between the source region 211 and drain region 212 of the transistor 206. Moreover, the light shielding film 196 shields a stray light transmitted between the pixel electrodes. Furthermore, the shielding light film 196 and the liquid crystal drive electrode 205 have planarly overlapping portions through the insulating film 195 to establish a capacitance, which can hold the voltage written in the pixel electrode 204.

Figures 26(a) to 26(e) show a process for manufacturing the light valve device using the semiconductor device according to a seventeenth embodiment of the present invention.

As shown in Figure 26(a), the insulating film 195 and the single crystal thin film, 193 are formed over a single crystal semiconductor substrate 215. Specifically, a single crystal silicon substrate is annealed, for example, after it has been doped with oxygen ions, so that the silicon substrate can be insulated with the silicon oxide while leaving the single crystal silicon layer on the surface of the silicon substrate. Alternatively, one silicon substrate can be removed while leaving the thickness of the thin film layer by adhering the silicon single crystal substrate formed on its surface with an oxide film and the silicon single crystal substrate.

Figure 26(b) shows an ordinary semiconductor miniaturization, by which the pixel electrode, the driver circuit and the control circuit are formed over the single crystal semiconductor layer 193.

In Figures 26(c), the single crystal semiconductor substrate 215 and the support substrate 192 are adhered through the polymer liquid crystal type liquid crystal layer 194. The support substrate 192 is made of an insulator such as glass or quartz.

In Figure 26(d), the single crystal semiconductor substrate 215 is removed while leaving its insulating layer 195 and single crystal semiconductor layer 193. The removing method to be used is exemplified by the polishing or etching method. At this time, the insulating layer is one for stopping the etching or for detecting the terminal point of the polishing.

In Figure 26(e), the shielding film 196 is formed to cover at least the channel region of the field effect transistor over the insulating film 195.

The light valve device can be achieved by the steps thus far described.

Figure 27 is a schematic exploded perspective view showing an eighteenth embodiment of the light valve device using the semiconductor device according to the present invention.

As shown, the light valve device is composed of the silicon semiconductor film layer 193, the glass support substrate 192 opposed to said semiconductor film layer 193, and the polymer liquid crystal type liquid crystal layer 194 arranged between said semiconductor film layer 193 and the support substrate 192. The silicon semiconductor film layer 193 is formed with the pixel electrode or drive electrode 205 for defining a pixel, and the driver circuit for exciting the drive electrode 205 in response to a predetermined signal. The support substrate 192 is formed on its surface with the common electrode 197 made of a transparent conductive film. Moreover, the driver circuit is made of an integrated circuit which is formed in the single crystal silicon semiconductor film layer 193. The integrated circuit contains a plurality of field effect type insulated gate transistors 206 which are arranged in a matrix shape. Each transistor 206 has its source electrode connected with the corresponding electrode 205, its gate electrode connected with a scanning line 208, and its drain electrode connected

with a signal line 207. Said integrated circuit further includes an X driver 199 connected with the column signal lines 207, and a Y driver 200 connected with the row scanning lines 208. The light shielding layer 196 covers the transistors or PN junctions of the semiconductor film layer 193, whose characteristics are changed under the influence of an incident light, through the insulating layer 195. Incidentally, the drive method of the present light valve device is similar to that which has been described in the fifteenth embodiment of the present invention.

In the light valve device described above according to the present invention, if a colour filter is formed to correspond to each pixel electrode at the substrate or opposite substrate side formed with the semiconductor thin film layer, a colour image can naturally be displayed.

As has been described hereinbefore, according to the present invention, the integrated circuit chip substrate, which is obtained by forming the pixel electrodes and the driver circuits integrally on the semiconductor single crystal thin film formed over the carrier layer by the use of the semiconductor miniaturizing technology, is used to form the light valve device. As a result, there arises an effect that it is possible to provide a light valve device having a remarkably high pixel density. Moreover, another effect is to provide a remarkably small-sized light valve device because it can be made as small as the integrated circuit chip. A further effect is that a circuit having a variety of functions as high as those of the LSI can be easily added because the integrated circuit technology can be applied to the single crystal thin film layer. A further effect is that not only the switching transistors but also the driver circuits can be simultaneously packaged by using a single crystal thin film. The light shielding film ensures the normal operation even if the incident light is intense. Furthermore, the light shielding film has a capacity between itself and the pixel electrodes to elongate the holding time of the signals written in the pixels and shields the electric field between the pixels to prevent the crosstalk between the pixels, thus raising a prominent effect that the image quality of the light valve device can be highly improved.

Figure 28 is a schematic enlarged section showing a video projector using the light valve device according to a nineteenth embodiment of the present invention. The video projector 230 has three active matrix transparent light valve devices 231 to 233 built therein. A white light emitted from a white light source lamp 234 is reflected by a reflecting mirror M1 and then resolved into red, blue and green lights by a trichromatic resolving filter 235. The red light is selectively reflected by a dichroic mirror DM1 and is then reflected by a reflecting mirror M2. After this, the red light is condensed by a condenser lens C1 until it is guided into the first light valve device 231. The red

light is modulated by the light valve device 231 in accordance with a video signal and is transmitted through dichroic mirrors DM3 and DM4. After this, the red light is magnified and projected to the front by a magnifying lens 236. Likewise, the blue light having passed the dichroic mirror DM1 is selectively reflected by a dichroic mirror DM2 and is condensed by a condenser lens C2 until it is guided into the second light valve device 232. Here, the blue light is modulated in accordance with the video signal and is guided through the dichroic mirrors DM3 and DM4 into a common magnifying lens 236. Moreover, the green light is transmitted through the dichroic mirrors DM1 and DM2 and is condensed by a condenser lens C3 until it is introduced into the third light valve device 233. Here, the green light is modulated in accordance with the video signal and is reflected toward the magnifying lens 236 by a reflecting mirror M3 and a dichroic mirror DM4. Thus, those primaries thus individually modulated the three light valve devices are finally synthesized by the magnifying lens 236 so that they are projected in a magnified two-dimensional image on the front. The light valve devices used have a size of an order of cm so that the various optical parts and the white light lamp can be accordingly small-sized. As a result, the overall shape and size of the video projector 230 can be made far smaller than those of the prior art.

Claims

1. A semiconductor device having a support layer (2) with transistor elements (5-7) provided thereon, characterised by a thin film layer (1) including a surface insulating film (3), a single crystal semiconductor thin film (4) disposed below said surface insulating film and having a source region (6), a drain region (7) and a channel forming region (5) for constituting each said transistor element, an insulating film (8) disposed on the side of the single crystal semiconductor thin film opposed to said surface insulating film for providing a gate insulator, an electrode film (9) disposed on the side of the insulating film opposed to said single crystal semiconductor thin film for providing a gate electrode of each said transistor element, and a back insulating film (10) disposed at least over the electrode film on the side thereof opposed to said insulating film, said support layer being fixedly adhered in face to face relation with said back insulating film.
2. A semiconductor device according to claim 1 characterised in that said support layer comprises a single layer (42) of an adhesive material.
3. A semiconductor device according to claim 1 or 2

characterised in that each said transistor element is connected by way of a through hole (16,32) in the surface insulating film with an electrode (17,31) formed over the surface insulating film.

4. A semiconductor device according to claim 1, 2 or 3 characterised by an additional gate electrode (18) formed over the surface insulating film in alignment with the channel forming region of each said transistor element.
5. A semiconductor device according to any preceding claim characterised by a light shielding film (20) arranged so as to cover at least the channel forming region of each said transistor element for preventing optical leakage current in the channel forming region.
6. A semiconductor device according to any preceding claim characterised by a capacitor electrode (19) formed over the surface insulating film in opposition to the drain region of each said transistor element so as to provide a capacitor element.
7. A process for manufacturing a semiconductor device characterised by a first step of forming an SOI substrate having a single crystal semiconductor thin film (22) laminated on a tentative substrate (20) through an insulating film (21); a second step of forming a semiconductor integrated circuit for said single crystal semiconductor thin film; a third step of adhering a support substrate (24,25) fixedly in face to face relation with the surface of the semiconductor integrated circuit opposite the side of the tentative substrate; a fourth step of removing the tentative substrate to expose the insulating film to the outside; and a fifth step of subjecting the exposed surface of the insulating film to a treatment including at least the forming of an electrode.
8. A process according to claim 7 characterised in that the first step of forming the SOI substrate includes thermally bonding a semiconductor substrate of single crystal silicon to the tentative substrate through the insulating film, and polishing the semiconductor substrate to form a thin film of the single crystal silicon.
9. A process according to claim 7 or 8 characterised in that the first step of forming the SOI substrate includes depositing a silicon nitride layer as a surface treatment on the tentative substrate, and depositing a silicon dioxide layer by chemical vapour deposition to form the insulating film.
10. A process according to claim 7, 8 or 9 characterised in that the third step of adhering the support

substrate includes releasing gas generated from the adhesive by way of through holes in the support substrate.

11. A light valve device comprising a drive substrate having drive electrodes (113) and drive circuits (114) for exciting said drive electrodes in response to predetermined signals; an opposed substrate (128) arranged opposite to said drive substrate; and an electro-optical material layer (127) arranged between said drive substrate and said opposed substrate, characterised in that said drive substrate includes a transparent insulating film layer (111) and a single crystal semiconductor thin film (112) formed over said transparent insulating thin film layer, said drive circuits include transistor elements (114) formed in said transparent insulating thin film layer, and said drive electrodes are integrally arranged on said single crystal thin film layer and electrically connected with said drive circuits whereby they are excitable by said drive circuits to act upon said electro-optical material layer for controlling the optical transparency of the same.
12. A process for manufacturing a light valve device having a semiconductor substrate, characterised by a first step of preparing a three layer substrate, in which a temporary substrate (151) and a single crystal semiconductor thin film layer (112) are laminated through a transparent insulating thin film layer (111); a second step of forming pixel electrodes (113) in portions of said three layer substrate from which the single crystal semiconductor thin film layer is selectively removed, and forming said single crystal semiconductor thin film layer with drive circuits composed of switch elements (114) and driver circuits (131,132) for supplying signals selectively to said switch elements; a third step of adhering a carrier substrate (122,123) on the surface of said three layer substrate which is formed with said pixel electrodes and said drive circuits; a fourth step of removing said temporary substrate to expose said transparent insulating thin film layer; a fifth step of forming through holes in predetermined locations in said exposed transparent insulating thin film layer and forming a metal film (152) on the exposed surface of said transparent insulating thin film layer; a sixth step of removing said metal film to form a light shielding layer for covering at least a portion of said drive circuits and forming an electrode pad connected with said drive circuits by way of said through holes to form said semiconductor substrate; and a seventh step of laminating and adhering the surface of said light shielding layer and an opposed substrate formed

with a transparent electrode so as to leave a gap between said substrates and filling up said gap with an electro-optical material.

13. An image projection system comprising a light source (234); a light valve device (231-233) for guiding light coming from said light source, said light valve device comprising a drive substrate having drive electrodes and drive circuits for exciting said drive electrodes in response to predetermined signals, an opposed substrate arranged opposite to said drive substrate, and an electro-optical substance layer arranged between said drive substrate and said opposed substrate; and an optical lens (C1-C3) for magnifying and projecting an image on said light valve device; characterised in that said drive substrate of said light valve device includes a transparent insulating thin film layer, a single crystal semiconductor thin film layer formed over said transparent insulating thin film layer, and a light shielding layer formed at that surface of said transparent insulating thin film layer which is opposed to the side of said single crystal semiconductor thin film layer, said drive circuit includes transistor elements formed in said transparent insulating thin film layer, said light shielding layer is formed to cover the active portions of said transistor elements, and said drive electrodes are integrally arranged on said single crystal thin film layer and electrically connected with said drive circuits so that they are excited by said drive circuits to act upon said electro-optical substance layer whereby to control the optical transparency of the same.
